Abstract

In scenarios of real-time data collection in long-term deployed Wireless Sensor Networks (WSNs), low-latency data collection and long network lifetime become key issue. We propose a Long-Lifetime and Low-Latency Data Aggregation Scheduling algorithm (L\textsuperscript{4}DAS) in wireless sensor networks. Firstly, we formally formulate the problem of long-lifetime and minimum-latency aggregation scheduling as a constrained optimization problem, and then propose an approximation algorithm for this problem by constructing a degree-bounded minimum height spanning tree as aggregation tree and designing a maximum interference priority scheduling scheme to schedule the transmission of nodes in aggregation tree. Finally, through the simulation and comparisons, we prove the effectiveness of the algorithm.

Keywords: WSNs, Data aggregation scheduling, Network lifetime, Long-lifetime, Low-latency

1. Introduction

Wireless Sensor Networks have been used for many long-term and real-time applications which require networks to operate long durations, as well as to transmit the sensed data to sink as soon as possible. Therefore, both maximizing lifetime and minimizing delay are the fundamental requirements. However, these two requirements are usually conflict with the limited battery power and communication bandwidth of sensor node. Sleep-wake scheduling \cite{1, 2} and data aggregation \cite{3} are the effective mechanisms to prolong the lifetime of energy-constrained sensor networks. However, both sleep-wake scheduling and data aggregation can also lead to additional data collection delay \cite{2, 3}. So, it is critical to research a problem of data aggregation scheduling with long-lifetime and low-latency in WSNs.

In WSNs, the Minimum-Latency Aggregation Schedule (MLAS) problem is to find a collision-free transmission schedule of data aggregation for all sensors such that the
total time latency for aggregated data to reach the sink is minimized. Chen, et al., in [6] proved that the problem of minimizing the latency of data aggregation is NP-hard. Many scheduling algorithms have been proposed to reduce the latency of data aggregation by using TDMA technology [4, 5, 6, 8]. Chen, et al., in [4] designed an algorithm named SDA based on Shortest Path Tree with a latency bound of \((\Delta - 1)R\), where \(\Delta\) is the maximum degree and \(R\) is the network radius. Huang, et al., designed an algorithm in [5] based on maximal independent sets which has an latency bound of \(23R + \Delta - 18\). Wan, et al., [6] proposed three algorithms: SAS, PAS and EPAS which have latency bounds of \(15R + \Delta - 4\), \(2R + O(\log R) + \Delta\) and \((1 + O(\log R / \sqrt{R}))R + \Delta\) respectively. Yu, et al., [7] and Xu, et al., [8] proposed a distributed scheduling method generating collision-free schedules with delay at most \(24D + 6\Delta + 16\) and \(16R + \Delta - 14\) time-slots respectively, where \(D\) and \(R\) is the network diameter and radius. These algorithms which do not consider lifetime scheduling problem theoretically prove the upper-bound on latencies, but this upper bound is far too pessimistic compared to the typical practical behavior of their algorithm. Malhotra, et al., [9] proved that a lower bound on the schedule length for a given tree is \(\max \{i \xi_i + d_i : i = 1, 2, \ldots, N\}\), where \(\xi_i\) and \(d_i\) are the number of children and hop distance from the sink, respectively, for node \(i\). Their scheme got the better performance than the previous algorithms by constructing a balanced shortest path tree (BSPT) and using a ranking-based heuristic scheduling.

Energy efficiency is the biggest challenge in designing long-living sensor networks. Wu, et al., [10] proved that finding a maximum lifetime arbitrary tree is NP-complete, and proposed an approximation algorithm that produces a sub-optimal tree. Luo, et al., [11] studied the problem of maximizing the lifetime for the shortest path aggregation trees by reducing it to a general version of semi-matching problem. Malhotra, et al., [9] constructed a BSPT to prolong network lifetime which balance the number of children per node by assigning nodes from level \(h+1\) to the parents at level \(h\) such that every parent has an equal number of children. However, the network lifetime in [9] determined by network architecture and the number of nodes, and the non-leafy characteristic of BSPT is not conducive to reducing scheduling length.

In this paper, we propose a Long-Lifetime and Low-Latency Data Aggregation Scheduling (L4DAS) algorithm in WSNs. Our main contributions are as follows: (1) we construct a degree-bounded minimum height spanning tree as aggregation tree which provides a long network lifetime and is conducive to reduce scheduling length and, (2) we propose a maximum interference priority scheduling algorithm to schedule the transmission of nodes such that the latency is approximately minimized, and (3) we carry out extensive simulations to verify our algorithms, and the results show that our algorithm greatly outperforms the state-of-art schemes.

The rest of the paper is organized as follows. Section 2 describes system models, assumptions, and problem formulation. We present an algorithm for construction data aggregation tree with efficient lifetime and minimum radius in Section 3. A greedy maximum TDMA scheduling algorithm is also proposed in Section 3. Section 4 presents the simulation results and analysis. Section 5 concludes the paper.
2. System Model and Problem Statement

2.1 System Model and Definitions

We consider a WSN consisting of $N$ sensor nodes $v_1, v_2, ..., v_N$ and sink node $v_s$. We assume that all nodes have the same transmission range $r$ and interference range $r_i$. We use an undirected graph $G(V, E)$ to represent this WSN, where $V = \{s, v_1, v_2, ..., v_N\}$ denotes the set of nodes and $E$ denotes the set of edges, i.e., there is an edge $(v_i, v_j) \in E$ whenever their Euclidean distance $\|v_i - v_j\| \leq r$.

We consider the protocol interference model in which concurrent transmissions on two edges $u \rightarrow v$ and $p \rightarrow q$ conflict with each other if and only if $v = q$, $\|p-v\| \leq r_i$ or $\|q-u\| \leq r_i$ [7, 8, 12]. All sensors are homogeneous which have the same energy $E_{node}$ and consume energy $E_{tx}$ and $E_{rx}$ for transmitting and receiving one bit data respectively. We adopt a perfect data aggregation model and TDMA-based scheduling protocol which offer the advantage of permitting nodes to enter into sleep mode during inactive periods so as to efficiently eliminate collisions and prevent overhearing. In order to facilitate the description, we give the following definitions:

Definition 1. Link Conflict. Under the protocol interference model, there exists a Link Conflict between link $u \rightarrow v$ and $p \rightarrow q$ if and only if $v = q$, $\|p-v\| \leq r_i$ or $\|q-u\| \leq r_i$.

Definition 2. Node Conflict. If there exists a link conflict between link $u \rightarrow v$ and $p \rightarrow q$, we call sender $u$ and $p$ are Node Conflict, or call that sender $u$ conflict with sender $p$.

Definition 3. Round. A Round is defined as the process of gathering data from all nodes to the sink which is equivalent to a TDMA schedule period consisting of $T$ time slots. The duration of each round is called the scheduling latency. At each time slot, all senders and their corresponding parent nodes are scheduled in active state while the remaining nodes in sleep state.

Definition 4. Network Lifetime. The network lifetime is defined as the lifetime of the first dead node in the network. In data aggregation scheduling, we usually need to construct a data aggregation tree, so the network lifetime will be the lifetime of data aggregation tree. The lifetime $L(T_{DA})$ of the data aggregation tree $T_{DA}$ is

$$L(T_{DA}) = \min_{i=1,2,3, ..., N} \left[ \frac{E_{node}}{KE_{tx}D(T_{DA}, v_i) + K(E_{tx} - E_{rx})} \right]$$

where $D(T_{DA}, v_i)$ is the degree of node $v_i$ in $T_{DA}$, $K$ is the number of bits generated by each node in a round.

2.2 Problem Statement

We formulate the long-lifetime and low-latency data aggregation scheduling problem as a constrained optimization problem. Table 1 lists the symbols used in this optimization problem.
Table 1. Symbols and Meanings

The objective function of this problem becomes Minimize \( T \), subject to the following constraints,

\[
\begin{align*}
& (a) \sum_{v_i \in N_i} \sum_{t=1}^T f_{(v_i, v_j)}^{(i')} = 1 \quad i \in \{1, 2, \ldots, N\} \\
& (b) \sum_{v_i \in N_i} \sum_{t=1}^T f_{(v_i, v_j)}^{(i')} = 0 \quad i \in \{1, 2, \ldots, N\} \\
& (c) \sum_{v_i \in N_{R(v_i)}} f_{(R(v_i), v_i)}^{(i')} = 0 \quad i \in \{1, 2, \ldots, N\} \\
& (d) \sum_{v_j \in N_{R(v_i)}, v_j \neq v_i} \sum_{v_k \in N_j} f_{(v_i, v_k)}^{(i')} + \sum_{v_j \in N_{R(v_i)}, v_j \neq v_i} \sum_{v_k \in N_{R(v_i)}, v_k \neq v_i} f_{(v_j, v_k)}^{(i')} = 0 \quad i \in \{1, 2, \ldots, N\} \\
& (e) \sum_{v_i \in CHD(v_i)} \sum_{t=1}^T f_{(v_i, v_j)}^{(i')} \leq D - 1 \quad i \in \{1, 2, \ldots, N\}
\end{align*}
\]

Constraint (a) enforces a single transmission per node in each round. Constraint (b) ensures that, once node \( v_i \) transmits, it can no longer receive data from its children nodes in the same round. As shown in Figure 1, node \( v_i \) can transmit data only after it has received data from all its children. Constraint (c) guarantees that node can not transmit and receive simultaneously at the same time slot, i.e. half-duplex operation. In Figure 1, \( R(v_i) \) can not transmit data to \( v_i \) when \( v_i \) is transmitting data to \( R(v_i) \). Constraint (d) ensures requirement that there can be no interference at the recipient node, \( i.e. \) in Figure 1, when a link \((v_i, R(v_i))\) is being scheduled at some time slot, link \((v_i, v_j)\) and link \((v_p, v_q)\) can not be scheduled at the same time slot. Constraint (e) guarantees that each node at most has \( D - 1 \) children nodes. This scheduling problem has been proved as a \( NP \)-hard problem [4]. We propose an approximation algorithm for this problem. We first construct a degree-bounded minimum height spanning tree as aggregation tree, and then design a maximum interference priority scheduling scheme to schedule the transmission of nodes in aggregation tree. The details will be presented in the following section.
3. Main Design

3.1 Data Aggregation Tree Construction

We construct the data aggregation tree through two phases. First, we break up the graph into clusters with the diameter equaling to transmission range $r$ and construct a cluster spanning tree respecting the degree constraint $D$ in each cluster. Then we construct a global tree over the clusters and connect the spanning tree in each cluster to the global tree.

Given $G(V, E)$, depending on the size of the deployment area and transmission radius, we first partition $V$ into pairwise disjoint sets [13, 14]:

1. $V = V_1 \cup V_2 \cup \ldots \cup V_m$, for $\forall i, j \in \{1, 2, \ldots, m\}$, $V_i \cap V_j = \emptyset$;
2. $\forall v_p, v_q \in V_i$, $i \in \{1, 2, \ldots, m\}$, $\|v_p, v_q\| \leq r$;

where $V_i$ ($i \in \{1, 2, \ldots, m\}$) is the set of nodes in cluster $i$. We partition $V$ by tessellating the deployment area into a set of hexagonal clusters each of side length $r/2$ and assigning each node to a unique cluster whose center is closest to the node. We then choose a representative for each cluster to constitute a set $R = \{u_1, u_2, \ldots, u_m\}$ where $u_i \in V_i$, $i \in \{1, 2, \ldots, m\}$. The global tree will be constructed by these representatives. If some representatives can not connect with each other, we choose some connecting nodes $C = \{c_1, c_2, \ldots, c_n\}$ to connect them. The global tree should be constructed satisfying the following constraint,

$$\min_{R \subseteq V} \max_{u \in R} \text{hops}(u, v_i)$$

$$\text{s.t.} \quad \max_{u \in R} \deg(u) \leq D - 1$$

where $\text{hops}(u, v_i)$ is the hop distance from $u$ to sink $v_i$, $\deg(u)$ is the degree of $u$. As shown in Figure 2, each circle represents a cluster. The nodes from $v_1$ to $v_6$ are representatives which correspond to 6 clusters respectively. $c_1$ and $c_2$ are connecting nodes. Dotted lines with arrows connect these nodes together to form the global tree. In each cluster, we construct a cluster spanning tree rooted at representative node while respecting the degree constraint $D$. The Algorithm of constructing data aggregation tree is shown in Algorithm 1.
Algorithm 1 Constructing Data Aggregation Tree

**Input:** \(G(V,E)\), sink, \(D \geq 2\);

**Output:** aggregation tree \(T_{DA}\).

**Step 1:** Partition \(V\) into pairwise disjoint sets \(V_1, V_2, \ldots, V_m\).

**Step 2:** Choose representatives \(R = \{u_1, u_2, \ldots, u_m\}\) and connecting nodes \(C = \{c_1, c_2, \ldots, c_n\}\) satisfying formula (3);

**Step 3:** Construct global tree \(T_G\) rooted at sink by connecting nodes in both \(R\) and \(C\); Run Step 4 to Step 6 for each cluster, construct \(m\) cluster spanning trees;

**Step 4:** For cluster \(i\) , \(V_i = \{v_{i1}, v_{i2}, \ldots, v_{in}\}\) and representative node \(u_i\) , initialize spanning tree \(T_i = (V_{ti}, E_{ti})\), \(V_{ti} \leftarrow \{u_i\}\), \(E_{ti} \leftarrow \emptyset\);

**Step 5:** Choose \(n\) nodes \((v_{i1}, v_{i2}, \ldots, v_{in})\) from \(V_i\) as children nodes of \(u_i\), where \(n = D - \deg_G(u_i)\) (\(\deg_G(u_i)\) is the degree of node \(u_i\) in the global tree \(T_G\)), i.e. \(V_{ti} \leftarrow V_{ti} \cup \{v_{i1}, v_{i2}, \ldots, v_{in}\}\), \(E_{ti} \leftarrow E_{ti} \cup \{(v_{i1}, u_i), (v_{i2}, u_i), \ldots, (v_{in}, u_i)\}\);

**Step 6:** Choose nodes from \(\{v_{i1}, v_{i2}, \ldots, v_{in}\}\) as parent nodes, then choosing \(D - 1\) children nodes from \(V_i / \{v_{i1}, v_{i2}, \ldots, v_{in}\}\) for each parent node, repeat this process until all nodes in \(V_i = \{v_{i1}, v_{i2}, \ldots, v_{in}\}\) are scheduled;

**Step 7:** Combine global tree \(T_G\) with all cluster spanning trees, \(T_{DA} = T_g \bigcap \bigcup_{i=1}^m T_i\).

3.2 Aggregation Scheduling

A data aggregation schedule with delay \(T\) can be defined as a sequence of sender sets \(S_1, S_2, \ldots, S_T\) satisfying the following conditions:

\(S_i \cap S_j = \emptyset, \forall i \neq j;\)

\(\forall v_i, v_j \in S_i, l = 1, 2, \ldots, T, v_i\) and \(v_j\) do not conflict with each other;

\(\text{At time slot } k, \text{ each sender in } S_i \text{ transmits data to its parent node in } V - \bigcup_{j=1}^k S_j\)
In this subsection, we design a maximum interference priority scheduling scheme to schedule the nodes in aggregation tree. We give some definitions as follows:

Definition 5. **Eligible Schedule Set.** At a time slot, nodes are eligible to be scheduled as senders if they are leaf-nodes not being scheduled at earlier time slot or intermediate nodes whose all children nodes have been scheduled at earlier slots. We define a set $F$ of such nodes as an eligible schedule set.

Definition 6. **Interference Intensity.** When a node is scheduled to transmit, the number of receivers which can be interfered by this node is defined as the interference intensity of this node. For an eligible schedule set $F_i$ and the sets $S_1, S_2, \ldots, S_{i-1}$ that has been scheduled at earlier $i-1$ slots, we can calculate the interference intensity $DI(u)$ of node $u$ (for $\forall u \in F_i$) as

$$ DI(u) = \left| \text{Nei}_u \cap (V - \bigcup_{j=1}^{i-1} S_j) - \text{Nei}_u \cap F_i - \{ \text{par}_u \} \right| $$

where $\text{Nei}_u$ is the neighbors of node $u$ in graph $G$, $\text{par}_u$ is the parent node of node $u$ in aggregation tree, and $V - \bigcup_{j=1}^{i-1} S_j$ represents the set of nodes that have not been scheduled at time slot $i$.

For the eligible schedule set $F_i$ at time slot $i$, we first assign the node with the largest interference intensity to sender set $S_i$, then choose the node that has the largest interference intensity in $F_i - S_i$ and also do not conflict with the nodes in $S_i$. We continue this process until there do not exist node in $F_i - S_i$ satisfying conflict-free schedule. **Algorithm 2** gives the processes of schedule.

**Algorithm 2 Aggregation Scheduling**

**Input:** $G = (V, E)$, data aggregation tree $T_{DA}$, sink;  
**Output:** Sets of sender $S_1, S_2, \ldots, S_T$;  
**Initialize:** $t = 1, i = 1$;  
**Repeat executing Step 1 to Step 4 until all nodes have been scheduled.**

**Step 1:** Calculate the eligible schedule set $F_i$ depending on Definition 5 at time slot $i$;  
**Step 2:** $v = \arg\max_{u \in F_i} DI(u)$, $S_i = \{v\}$;  
**Step 3:** if $p = \arg\max_{u \in (F_i - S_i)} DI(u)$ and node $p$ do not conflict with the nodes in $S_i$, $S_i \leftarrow \{p\}$;  
repeat executing **Step 3** until there do not exist node in $F_i - S_i$ satisfying conflict-free schedule;  
**Step 4:** Output $S_i$, $i = i + 1$

4. **Simulation Results**

We evaluate the performance of our algorithm using simulations. We randomly deploy sensor nodes in a $200m \times 200m$ field with a sink located at $(100, 100)$. All sensor nodes have the same transmission range and interference radius, i.e., $r = r_t$. We generate 30 random networks and present the averaged results for performing comparisons. Table 2 shows the simulation parameters.
Table 2. Simulation Parameters

For aggregation latency, we compare $L^4$DAS with WIRES [9] and LDAS [12]. Transmission range $r$ is fixed to 25m, the number of nodes varies from 400 to 1000 with an increment of 50. As can be seen from Figure 3, both $L^4$DAS and LDAS outperform WIRES. When the number of nodes is less than 650, LDAS outperforms $L^4$DAS. The reason is that when node density is not high, the aggregation tree of $L^4$DAS has higher height that can increase the low-bound of latency [9]. However, with the increasing of node density, the degree of nodes (especially sink) in LDAS increases rapidly which causes the low-bound of latency increases. So, when the node density exceeds a certain value, $L^4$DAS will always outperform LDAS.

In Figure 4, we give the latency of $L^4$DAS with different $r$. As transmission range increases, the potential for conflict between the nodes increases, which leading to increase latency. In Figure 5, $N$ varies from 500 to 1000 with an increment of 50, while $r$ takes three values 25, 30 and 35 respectively. It is indicated from the histogram that with the increment of the number of nodes and the transmission range, the improvement of our algorithm will be larger. These results indicate that our algorithm is greatly preferred for large scale and high density WSNs.

![Figure 3. Latency with Different Number of Nodes](image)

![Figure 4. Latency of $L^4$DAS with Different $r$](image)
Using the same simulation parameters as Figure 3, Figure 6 shows the network lifetime changes with the different number of nodes. It can be seen that our algorithm outperforms LDAS and WIRES. With the changes in the number of nodes, the network lifetime of our algorithm changes little while WIRES fluctuates larger.

![Figure 5. Latency with Different Number of Nodes and Transmission Range](image1)

![Figure 6. Network Lifetime with Different Number of Nodes](image2)

Figure 7 shows the data aggregation trees with 500 nodes of three algorithms. The leaf nodes of our algorithm and LDAS are more evenly distributed in the deployment area which is prone to schedule more nodes for parallel transmission in a time slot. The degrees on our algorithm and WIRES are more evenly distributed so as to provide longer lifetime than LDAS. However, due to being impacted by the network topology and node distribution, the degree of some nodes in WIRES is very high.

5. Conclusions and the Future Works

In this paper, we have investigated the data aggregation problem and considered its latency and network lifetime for WSNs in scenarios of real-time and long-term applications. We formulated the problem as a constrained optimization problem. Then, we proposed an approximation algorithm for this problem based on constructing a data aggregation tree and designing a maximum interference priority scheduling scheme. Finally, through the simulation and comparisons, we proved that our algorithm outperforms the start-of-art schemes. In the future, we will extend our scheduling algorithm for the more realistic physical interference model. We will also research the distributed algorithms for constructing aggregation tree and scheduling the transmission of nodes.
